Low Education as a Risk Factor for Undiagnosed Angina

Michael M. McKee, MD, MPH, Paul C. Winters, MS, and Kevin Fiscella, MD, MPH

Background: Early awareness, recognition, and treatment of angina can help prevent or delay an acute myocardial infarction and potentially delay death. A patient's educational level may affect a physician's diagnosis of angina and/or a patient's symptom recognition. The objective of this study was to determine whether low education is a risk factor for undiagnosed angina.

Methods: This was a cross-sectional observational study based on data from the National Health and Nutrition Examination Survey 2001 to 2008, providing a nationally representative sample of adults ≥ 40 years of age with angina based on physician diagnosis, presence of angina symptoms based on the Rose Questionnaire, or both. Educational attainment (high school or less vs more than high school) was the independent variable of interest. Undiagnosed angina (angina symptoms in the absence of angina diagnosis) was the dependent variable. We used logistic regression to control for age, sex, race/ethnicity, income, and health care visit during the past year.

Results: Low education was associated with undiagnosed angina (odds ratio: 1.43; 95% confidence interval: 1.01–2.03). Other undiagnosed angina predictors included being female, being black, and having no health care visit during the past year.

Conclusions: Low education is associated with undiagnosed angina. These results underscore the need for providers to ask about angina symptoms and confirm patients' understanding of their angina diagnosis among those with low education. (J Am Board Fam Med 2012;25:416–421.)

Keywords: Angina Pectoris; Cross-Sectional Studies; Education; Health Knowledge, Attitudes, Practice

More than 6 million Americans are affected by angina pectoris and it is the primary symptom in roughly half of patients with coronary artery disease.¹ According to 2008 national data, 4.1% of adults reported that they were informed of an an-

gina or CAD diagnosis.² Early recognition and treatment of angina can help prevent or delay the onset of an acute myocardial infarction and potentially death, yet many lifesaving treatments such as thrombolytic therapy, aspirin, and nitroglycerin are not used (or their use is delayed) because of patients' failure to recognize cardiac symptoms.³

Low educational attainment is associated with low health literacy and with less effective health communication, which affects patients' abilities to convey pertinent health information to their providers. Low education also is associated with lower awareness and comprehension of physician diagnoses and recommendations.⁴ Adults who completed high school or less display lower literacy,⁵ lower health literacy,^{6,7} and lower cardiac health literacy (ie, cardiac symptom recognition).⁸ In a 2005 national sample, low education was associated with lower recognition of 5 heart attack symptoms.⁹ There is a growing body of evidence linking low education to worse cardiovascular outcomes.^{2,10–12} Given the association between low education and

low cardiac health literacy, we hypothesized that individuals with low education would more often report angina symptoms that were undiagnosed than would those with higher education.

Methods

Sample

We used 2001 to 2008 data from the National Health and Nutrition Examination Survey (NHANES), a nationally representative, stratified, multistage probability sample of the civilian noninstitutionalized population of the United States. Since 1999, NHANES has been conducted on a continuous basis, with data released in 2-year cycles. Data collection methods include an interviewer-administered questionnaire using computer-assisted personal interview technology and physical examinations performed in mobile examination centers. In addition, NHANES oversampled African Americans, Hispanics, and persons aged 60 years and older.¹³ Our study sample included 1028 adults (497 men and 531 women) aged 40 years and older with either diagnosed or undiagnosed angina (details provided later) with complete data on age, race, sex, income, and health care variables.

Measures

Angina

We assessed angina in 2 ways. The first was based on an affirmative response to the question, "Has a doctor or other health professional ever told you that you had angina, also called angina pectoris?" The second was based on the presence of angina symptoms using the Rose Questionnaire,¹⁴ a standardized and validated assessment tool designed to differentiate cardiac from noncardiac chest pain. It has been used widely in a variety of cardiovascular epidemiologic studies over the past several decades^{10,15} within multiple countries and among persons of different races, sexes, languages, educational levels, and occupations.^{10,16–19} It has fair sensitivity and specificity for angina compared with various clinical assessments: clinical judgment (sensitivity of 81% and specificity of 97%),¹⁶ thallium scintigraphy (sensitivity of 40% to 50% and specificity of 56% to 77%),^{20,21} coronary angiography (sensitivity of 50% and specificity of 75%),²² and exercise electrocardiography (sensitivity of 57% and specificity of 47%).²² The 9 questions on the Rose Questionnaire are shown in Table 1.

Table 1. Questions on the Rose Questionnaire

1.	Have you ever had any pain or discomfort in your chest?
2.	Do you get it when you walk uphill or hurry?
3.	Do you get it when you walk at an ordinary pace on level ground?
4.	What do you do if you get it while you are walking?
5.	Do you stop or slow down or continue at the same pace?
6.	If you stand still, what happens to it?
7.	Is the pain or discomfort relieved or not relieved?
8.	How soon is the pain relieved?
9.	Where is the pain or discomfort located?

We used NHANES criteria to identify those with angina based on responses to this questionnaire: chest pain or discomfort (yes to question 1) that fulfilled all the following criteria: (1) was brought on by exertion (yes to either question 2, 3, or both); (2) forced the subject to slow down or stop (question 4); (3) was relieved if the subject did so (yes to question 5), (4) was relieved within 10 minutes (question 6), (5) was located in the central or left anterior chest (question 9).

Undiagnosed angina. We defined undiagnosed angina as a dependent variable based on the presence of angina symptoms in the absence of a physician diagnosis.

Low education. Self-reported educational attainment was our main independent variable. We operationalized it as high school education or less (low education) and more than high school education (referent).

Covariates

We included self-reported demographic covariates: age (40–54 years, 55–64 years, ≥65 years); sex (male, female); race/ethnicity (Mexican American/other Hispanic, non-Hispanic white, non-Hispanic black, other); and family poverty income ratio (federal poverty income thresholds that account for household size). We assessed health care access based on the participant's report of whether they had seen a doctor/health professional during the past year (yes/no).

Statistical Analysis

NHANES uses a complex sampling design involving stratification, clustering, and oversampling of certain groups that results in unequal probability of selection. The statistical analyses incorporated stra-

tum, primary sampling units, and appropriate interview sampling weights to produce unbiased estimates of the noninstitutionalized US population.²³ We used a subpopulation statement in SUDAAN software (RTI International, Research Triangle Park, NC) to generate estimates for the US population aged 40 years and older. Bivariate associations were determined using χ^2 tests. We assessed the independent association between low education and undiagnosed angina using logistic regression that controlled for demographics (sex, age, race/ethnicity, income, and education) and a health care-related variable (health care during past year). All statistical analyses were conducted using SAS-callable SUDAAN version 10.0.1 and SAS version 9.2 (SAS Institute, Inc, Cary, NC).

Results

The final sample included 1028 adults, of whom 359 had angina symptoms but reported no previous diagnosis of angina reported by their physicians.

Persons with undiagnosed angina were younger and more often women, black, and less likely to have seen a physician/health care professional during the past year compared with those without undiagnosed angina (Table 2). In an adjusted analysis, low education was significantly associated (odds ratio [OR], 1.43; 95% confidence interval [CI], 1.01–2.03) with undiagnosed angina (Table 3). Other significant predictors of undiagnosed angina included being female (OR, 1.95; 95% CI, 1.36–2.81), black (OR, 2.56; 95% CI, 1.67–3.93), and not having seen a physician/health care professional during the past year (OR, 2.81; 95% CI, 1.53–5.16). There were no significant interactions between education and other variables in the model.

We examined the extent to which having had a health care visit during the past year affected our findings. When we excluded this variable from our model, there was little change in the risk associated with low education (OR, 1.44; 95% CI, 1.02–2.03).

Discussion

In national survey of adults 40 years of age and older, we found that low education was associated with a 43% greater likelihood of undiagnosed angina. These effects persisted after controlling for age, sex, race, income, and having a physician visit during the past year. These findings are consistent with previous studies suggesting that low education may pose awareness and health communication issues, resulting in possible diagnosis errors and treatment delays.^{24,25} To our knowledge, these findings, based on national data using a validated measure for angina symptoms, are novel.

Our data do not indicate why low education is associated with undiagnosed angina symptoms. Our analysis controlled for having had a visit with health care provider within the past year, so having a recent physician visit is unlikely to be the sole explanation. Potentially, this association reflects low patient health literacy and resulting breakdowns in patient–provider communication. There is a strong association between low education and

low health literacy.^{6,7,26} Patients with low education are less likely to associate angina symptoms with heart disease.^{8,9} Clinicians may not appreciate that patients with low education are describing angina or may not clearly communicate their diagnosis to the patients. Physicians often use medical jargon that is poorly understood, particularly by patients with low health literacy.^{27,28} Other communication barriers include limited patient knowledge, patient embarrassment when asking questions, and suboptimal physician communication behavior.²⁹ When caring for patients with low education, physicians tend to listen less, provide less reassurance, underestimate the information patients desire, fail to engage the patient in shared decision making, offer patients too little health information, and display less empathy.^{30,31} For these reasons, we suspect that our results may reflect communication failures between physicians and their patients with low education.

Other patient demographic characteristics besides low education are also significantly associated with undiagnosed angina. These include being female, black, and not having seen a physician/health care professional during the past year. Although these reflect post hoc findings warranting replication through further study, they suggest that clinicians be especially attuned to unrecognized angina among these groups.

Less than 20% of women older than age 35 are aware that cardiovascular disease is a major cause of death among women.³² The Atherosclerosis Risk in Communities study, which used the Rose Questionnaire, revealed higher rates of angina among women compared with men.³³ Undiagnosed angina may be attributable to the language used during physician–patient encounters and inaccurate physician beliefs. Women ask more questions than men and try to retrieve more medical information but are less likely to be diagnosed as suffering from cardiovascular disease and are more likely to have their symptoms attributed to emotional or psychosomatic causes.³⁴

Despite higher burdens in cardiovascular diseases, blacks lag behind whites in cardiovascular disease recognition and awareness.^{2,33} Cardiovascular disparities among blacks are largely attributable to lower educational attainments and more risk factors, particularly hypertension.¹¹

Individuals older than 55 years of age were less likely to have undiagnosed angina compared with

individuals aged 40 to 54 years. This may be explained by several factors. Increasing age is associated with greater risk for cardiovascular disease, including angina.² The association of older age with greater likelihood of diagnosis may increase cardiovascular awareness among individuals in this age group. In addition, physicians also may have higher suspicion for angina and cardiovascular diseases for people in this age group.

Low education is associated with higher risk of developing angina and worse treatment and survival rates for both fatal and nonfatal cardiac events.¹ Thus, it is critical for physicians to be cognizant of the communication needs of persons with low education and to employ principles of clear communication, including teach-back.^{35,36} Specifically, providers and staff can communicate more effectively with less educated patients using the following steps: providing patients with adequate time and opportunity to voice their concerns and describe their symptoms; showing respect, including listening attentively; encouraging the patient to ask follow-up questions; rephrasing complex questions or terms into plain language; using appropriate pictures and graphics to enhance patients' comprehension of the material being discussed; encouraging the patient to explain their understanding in their own words³⁷; and actively engaging the patient in decision making.

Health information provided by physicians can be reinforced through public health programs and community outreaches that target persons with low education using simple and informative health messages about cardiac symptoms. Information also should include steps to take if cardiac symptoms occur, including contacting emergency medical services immediately.³⁸

Our findings are subject to several limitations. Data are self-reported and potentially subject to recall and reporting bias. No cause and effect can be established because of the nature of the cross-sectional design. We cannot pinpoint where breakdowns in communication occurred. Further study is needed to determine whether higher prevalence of unrecognized angina among those with low education results from patients failing to report symptoms or from clinicians failing to ask about symptoms, recognize symptoms, or both.

Most participants likely completed their formal education more than 20 years ago. However, the effect of educational attainment on literacy persists

over time. National data show a similar pattern between years of education and reading ability regardless of age.³⁹ Finally, we cannot exclude the possibility that other factors not accounted for in our model may confound our results.

Conclusions

Our findings show that among a national sample of adults with presumed angina, low education is associated with undiagnosed angina. Potentially, this may contribute to worse cardiovascular outcomes for this group. Additional research is needed to determine the reasons why low education is associated with undiagnosed angina and which interventions are mostly likely to improve diagnosis. Physicians should ask about the presence of angina symptoms, particularly among adults with low education, including women, blacks, and those who have not received health care during the past year.
