

Diffusion of Breast Cancer Risk Assessment in Primary Care

Carmen E. Guerra, MD, MSCE, Melani Sherman, BA, and
Katrina Armstrong, MD, MSCE

Background: Physicians who provide primary care to women have the opportunity to identify patients at high risk for breast cancer who are candidates for risk reduction strategies. Our objective was to determine the prevalence and determinants of the adoption of breast cancer risk assessment by primary care physicians.

Methods: A cross-sectional survey of a nationally representative random sample of 351 internists, family practitioners, and obstetrician-gynecologists. We used a questionnaire that assessed knowledge, attitudes, discussion of breast cancer risk, use of software to calculate breast cancer risk, and ordering of *BRCA1/2* testing.

Results: Eighty-eight percent of physicians reported discussing breast cancer risk at least once during the previous 12 months; 48% had ordered or referred a patient for *BRCA1/2* testing; and 18% had used a software program to calculate breast cancer risk. Physicians who had used *BRCA1/2* testing or discussed breast cancer risk factors were more likely to be obstetrician-gynecologists and not in a solo practice; the use of risk software was also more common among obstetrician-gynecologists but was also associated with having a family member with breast cancer and a greater knowledge about breast cancer risk. Having patients ask for risk information was associated with the discussion of risk factors but not with the other risk assessment strategies.

Conclusions: Diffusion of breast cancer risk assessment is occurring in primary care practices, with a greater adoption of *BRCA1/2* testing than of the use of risk assessment software. Adoption of these strategies seems to be related to the salience of breast cancer personally (for the physician) and within the practice, as well as the size of the practice, rather than attitudes about the risk assessment methods. (J Am Board Fam Med 2009;22:272–9.)

In the United States, an estimated 180,510 new cases of breast cancer will be diagnosed and 40,910 women will die of the disease in 2007.¹ For women

at average risk for breast cancer, the lifetime risk of being diagnosed with breast cancer is 13%.² However, breast cancer risk varies substantially among women, with 5-year risk ranging from <0.5% for a low risk woman in her 40s to >6% for a high-risk woman in her 70s.³

During the last 10 years, breast cancer risk assessment has become increasingly relevant to physicians who provide primary care to women for several reasons.⁴ The identification of women at high risk for breast cancer has taken on new importance with the Food and Drug Administration's approval of tamoxifen for breast cancer risk reduction in high-risk women in 1998 and the growing data supporting the effectiveness of prophylactic mastectomy among women at very high risk.^{5–7} Since the validation of the Gail model for individual breast cancer risk prediction,⁸ additional software programs for risk prediction have been developed, including the Claus, Couch, Shattuck-Eidens, Frank, and BRCAPRO models.^{9–13} The

development of testing for mutations in the major breast cancer susceptibility genes, *BRCA1* and *BRCA2*, has created risk-assessment tools that can both identify women at high risk for breast cancer but also provide information about ovarian cancer risk and cancer risk information for family members.¹⁴ Finally, evidence continues to link a woman's absolute risk of breast cancer to the risk/benefit ratio of many common decisions, including the use of postmenopausal hormone replacement therapy, the age at which to start mammography screening, and the appropriateness for high-risk screening programs including magnetic resonance imaging.^{15,16}

The US Preventive Services Task Force recently issued guidelines for genetic risk assessment and *BRCA1/2* testing in women with breast and ovarian cancer susceptibility.¹⁷ These guidelines, given a level B recommendation, state that referral for genetic counseling and consideration for breast cancer screening is recommended for women at increased risk of having *BRCA* (breast cancer gene) mutations. It is estimated that 2% of adult women in the general population meet a relatively strict definition of increased risk (2 first-degree relatives with breast cancer, one of whom was diagnosed at age 50 or younger; or a combination of 3 or more first- or second-degree relatives with breast cancer; or a combination of both breast and ovarian cancer among first- and second-degree relatives or a first-degree relative with bilateral breast cancer; or a combination of 2 or more first- or second-degree relatives with ovarian cancer; or a first- or second-degree relative with both breast and ovarian cancer; or a history of breast cancer in a male relative).¹⁵⁻¹⁷ However, an additional 5% to 6% of women are considered moderate risk for carrying a mutation, where *BRCA1/2* testing among 1200 women is estimated to prevent 1 case of breast cancer and 3 cases of ovarian cancer.¹⁷

Despite the recent developments in breast cancer risk assessment, little is known about primary care physicians' use of these new tools for risk assessment or their general discussion of breast cancer risk with their patients. One previous survey of primary care physicians in California investigated the use of tamoxifen and raloxifene and found that 86% of physicians said they initiate breast cancer risk reduction discussions at least half the time; 45% had referred a patient for genetic evaluation but did not measure the use of risk calculation software or ordering genetic tests.^{18,19} Thus,

the objective of this study was to assess the use of breast cancer risk assessment strategies among primary care physicians and to determine whether the use of *BRCA1/2* testing and risk prediction software was associated with the provider's personal characteristics, knowledge about breast cancer risk factors, or attitudes about breast cancer risk assessment. We hypothesized that use of these new strategies for risk assessment would be greatest among primary care physicians in whom breast cancer risk was most salient (physicians who had a family history of breast cancer or who saw a greater proportion of female patients) and who had greater knowledge of breast cancer risk factors and more positive attitudes about breast cancer risk assessment.

Methods

A cross-sectional, nationwide survey of a random sample of 1000 primary care physicians was conducted between June 2002 and June 2004.

Participants

A random sample of 1000 primary care physicians from obtained from the American Medical Association Masterfile. The sample was stratified by primary specialty as reported in the American Medical Association Masterfile to include an equal number of physicians whose primary practice was internal medicine, obstetrics/gynecology, or family medicine.

Procedures

The Institutional Review Board of the University of Pennsylvania approved this study. Study participants were mailed the questionnaire, a cover letter, and a reply envelope with prepaid postage. In the first mailing, participants were randomized to receive either a handwritten note, a \$5 incentive, or a handwritten note and a \$5 incentive. Two subsequent mailings, including the questionnaire, cover letter, and a \$5 incentive, were mailed to nonresponders. Physicians who had not responded to any of the mailings were called and offered a chance to complete the survey by phone or fax or to be mailed another packet if they preferred to complete it as a hard copy.

Survey Instrument

The PRECEDE model of health behavior (*P*redisposing, *R*einforcing, and *E*nabling Constructs in *E*ducational *D*iagnosis and *E*valuation), where be-

haviors are influenced by the presence or absence of predisposing, enabling, and reinforcing factors, was used to guide survey development.²⁰⁻²¹ The content areas of the questionnaire consisted of 4 sections: (1) physician demographics and practice characteristics; (2) knowledge about breast cancer risk; (3) attitudes about breast cancer risk assessment; and (4) physician behavior related to breast cancer risk assessment. The results of an additional survey content area related to primary care physicians' prescribing of tamoxifen for breast cancer prevention have been previously published.²²

Independent Variables

To assess knowledge of breast cancer risk factors, physicians were provided 7 pairs of clinical scenarios about women older than 40 years of age and were asked to identify the woman with the greater risk of developing breast cancer during her lifetime. Knowledge score was the proportion of the 7 cases for which the physician correctly identified the higher-risk case in the pair. To assess attitudes about breast cancer risk assessment, the questionnaire included 5 items assessing beliefs that risk assessment was too time consuming, that risk assessment could increase patient anxiety, that available methods of risk assessment were not accurate enough, that many patients asked for risk information, and that risk information might make low-risk women less likely to adhere to mammography screening. Response scales consisted of a 5-point Likert scale from "strongly agree" to "strongly disagree."

Items adapted from other physician surveys were used to assess sociodemographic and practice characteristics, including the number of primary care physicians in the practice, the average number of patients seen during a week by the physician responding to the survey, medical school affiliation, and the year of graduation from medical school.²³ We also asked whether any family member had been diagnosed with breast cancer and, if so, which family member.

Outcome Variables

The questionnaire measured the frequency at which physicians had used any software programs to calculate breast cancer risk, ordered or referred a patient for *BRCA1/2* testing, and discussed breast cancer risk factors during the previous 12 months.

Response scales for frequency of use questions were on a 5-point numerical scale that consisted of 0, 1 to 6, 7 to 12, 12 to 24, and >24 times. Because very few physicians had performed these behaviors multiple times, these responses were collapsed into 0 versus 1 or more.

Statistical Analysis

STATA SE software (version 8.0, StataCorp, LP, College Station, TX) was used to conduct all the statistical analyses. Descriptive statistics were calculated for physician and practice characteristics. Bivariate statistics using χ^2 and *t* tests were calculated to determine the relationship between physician characteristics, practice characteristics, physician knowledge of and attitudes toward breast cancer risk assessment, and each of the 3 outcome variables (discussion of breast cancer risk factors, use of software program to calculate breast cancer risk, and use of *BRCA1/2* testing). Logistic regression was used to adjust the associations between independent variables and the outcome variables (as dichotomous variables) for potential confounding and effect modification. Separate regression models were fit for each of the outcome variables. Covariates were selected based on a priori hypothesis deduced from our theoretical model or on a significant bivariate relationship. Each model adjusted for the known physician demographic and practice characteristics.

Results

Of the original sample of 1000 physicians, 248 physicians who had incorrect addresses, were no longer practicing, were not a primary care physician, had no female patients, or had died were excluded. Twenty-six physicians refused to participate. Of the remaining 726 questionnaires, 383 surveys were received after all attempts to recover the surveys. After excluding 32 incomplete surveys, a total of 351 questionnaires were available for analysis. The response rate was therefore 48.3%. Responders did not differ significantly from nonresponders in sex, region of the country, specialty, or type of degree (MD vs DO). However, responders had graduated from medical school more recently than nonresponders ($P < .01$).

The demographic and practice characteristics of the participating physicians are listed in Table 1. The mean age was 45.6 years and just over two-

PCP, primary care physician.

thirds were men. Forty-one percent practiced family practice, 39% internal medicine, and 19% obstetrics and gynecology. The mean number of years since graduating from medical school was 17.2. Approximately half had an affiliation with an academic medical center. Twelve percent of physicians had a close family member (parent, sister, spouse, daughter) who was diagnosed with breast cancer. Physician use of methods of breast cancer risk assessment during the previous 12 months revealed that 88% of physicians had discussed breast cancer risk with a patient within that time (26% 1 to 6 times, 13% 7 to 12 times, 13% 12 to 24 times, and 37% >24 times); 18% of physicians had used software to calculate breast cancer risk (11% 1 to 6 times, 3% 7 to 12 times, 1% 12 to 24 times, and 3% >24 times); and 48% of physicians had ordered or referred a patient for genetic testing for *BRCA1/2* mutations (33% 1 to 6 times, 8% 7 to 12 times, 4% 12 to 24 times, and 3% >24 times) during the last 12 months (Table 1). No physicians had used software to calculate breast cancer risk without discussing breast cancer risk and only 5 physicians had ordered or referred for genetic testing without reporting having discussed breast cancer risk factors.

The associations between physician and practice characteristics and breast cancer risk assessment strategies are shown in Table 1. Physician specialty was significantly associated with use of risk software and the use of *BRCA1/2* testing, with higher rates among obstetrician-gynecologists than internists or family practitioners. Physician specialty was also correlated with the discussion of risk factors; however, the association did not reach statistical significance. The number of primary care providers in the practice was significantly associated with the discussion of breast cancer risk factors, and there was a trend toward an association with the use of *BRCA1/2* testing. In addition, having a family member with breast cancer was associated with use of software to calculate risk. Not surprisingly, the use of each of these breast cancer risk assessment strategies increased with the average number of patients seen per week.

Knowledge of breast cancer risk factors was significantly higher among physicians who had used risk assessment software (mean knowledge score for software users, 0.71 vs 0.65 for nonusers; $P < .01$), but was not associated with having discussed breast cancer risk or with having ordered genetic testing for *BRCA 1/2* mutations (Table 2). The belief that

Knowledge			
Accuracy score (one point increase)	1.23 (0.26–5.69)	4.57 (1.17–17.08)	1.82 (0.73–4.55)

*Models include all the variables in the table as well as physician age, sex, and number of patients seen per week. All data provided as odds ratio (95% CI).

many patients asked for risk information was higher among physicians who had discussed breast cancer risk ($P < .01$) but was not significantly associated with use of software. None of the other attitudes were associated with the use of the breast cancer risk assessment strategies.

The results of the multivariate logistic regression models are shown in Table 3. Physician specialty remained strongly associated with each of the breast cancer risk assessment strategies, with greater odds among obstetrician-gynecologists than internists or family practitioners (for discussion of risk factors: odds ratio [OR], 3.35; 95% CI, 1.01–11.13; for the use of software: OR, 5.37; 95% CI, 2.54–11.55; and for the use of *BRCA1/2* testing: OR, 2.36; 95% CI, 1.24–4.49). Being in a solo practice was inversely associated with discussion of risk factors and use of *BRCA1/2* testing use (for discussion of risk factors: OR, 0.14; 95% CI, 0.04–0.56; for use of *BRCA1/2* testing: OR, 0.27; 95% CI, 0.07–0.96). There was a trend to an inverse association with the use of risk software but it did not meet statistical significance. In addition, the use of breast cancer risk software was associated with greater knowledge of breast cancer risk factors (OR, 4.57; 95% CI, 1.17–17.08) and having a family member with breast cancer (OR, 2.49; 95% CI, 1.27–6.32), whereas discussion of breast cancer risk factors was associated with having patients who asked for information about breast cancer risk (OR, 24.60; 95% CI, 3.23–188.94).

Discussion

Primary care physicians play a critical role in the identification of women at high risk for breast cancer and can provide a bridge to interventions that estimate and reduce risk.^{18,19,22,23} The tools and rationale for breast cancer risk assessment in primary care have grown substantially during the last 10 years. However, relatively little is currently known about the practice of breast cancer risk assessment in primary care. This study has several important new findings that have implications for breast cancer control.

First, diffusion of breast cancer risk assessment strategies varies substantially. The great majority of primary care physicians have discussed breast cancer risk with patients during the past year, half have ordered or referred a patient for *BRCA1/2* testing, and fewer than one-fifth have used software programs to calculate risk. Diffusion studies have shown that the distribution of individuals, based on the time of adoption of an innovation, generally follows a normal bell curve and can be separated into 5 categories: (1) innovators (the first 2.5% of individuals to adopt an innovation); (2) early adopters (the next 13.5%); (3) early majority (the next 34%); (4) late majority (the next 34%); and (5) laggards (the last 16% to adopt, if the innovation successfully diffuses through the population).²⁴ Based on our data, it seems that use of risk software in women's health remains confined to innovators and early adopters, whereas the use of *BRCA1/2*

counseling and testing has diffused to the early majority. Diffusion theory suggests that the probability that these technologies will eventually diffuse throughout primary care physicians depends, in part, on whether the early adopters take on the role of opinion leaders in this area as well as the intrinsic value and characteristics of these technologies and local environmental characteristics.^{24–28}

Although diffusion theory can provide some guidance when interpreting these data, it is important to recognize that consideration of *BRCAl/2* testing is currently recommended for a relatively small proportion of women and that patient preferences are an important determinant of appropriate testing use. As many more physicians discuss risk than refer for genetic testing, it is possible that the relatively lower rate of referral for genetic testing is related to patient decisions after risk discussions. Furthermore, providers may be making trade-offs between the different strategies for risk assessment, preferring to discuss risk factors in the office without incurring additional cost to undertaking the cost and potential complications of genetic testing. Although it is likely that most full-time primary care providers will have patients in their panels who meet criteria for *BRCAl/2* testing, decisions about genetic testing are complex and there is no gold standard for the desired rate of testing among high-risk women.

Second, physicians who have adopted novel breast cancer risk assessment strategies differ in several ways from their peers. Obstetrician-gynecologists seem to have adopted these strategies more rapidly than either internists or family practitioners, perhaps because a greater proportion of their care is related to women's health, making breast cancer more salient in their decision making. Early adopters of risk software are more likely to have a family member with breast cancer, another factor that may increase the salience of breast cancer to the individual physician. This finding echoes an earlier survey of California primary care providers that found physicians were more likely to have referred a woman for genetic counseling if they had more cases of breast cancer in their practice.¹⁹

The strength of this study is that it sampled a nationally representative sample of primary care physicians. The limitations of this study include the relatively low response rate of 49%, despite

multiple mailings and reminders. Although this response rate is close to the average response rate of 54% (SD, 17%) found in a 1997 review of physician surveys published in medical journals, nonresponders may have differed from responders in ways that may have influenced our results.^{29–32} This overestimation is likely to be lower for breast cancer risk assessment behaviors because there are no mandates for its performance in primary care practice (in contrast to cancer screening), but we did not have the means to confirm physician practice patterns. Several factors that may have influenced adoption were not included in our survey and their influence on the use of risk assessment could not be determined. In particular, the availability of computers and use of an electronic medical record may be important determinants of the use of software programs to calculate risk. Finally, the measures used in this study were developed specifically for this study and we lack of formal psychometric information for the instrument.

Despite these limitations, this study provides new insights into the use of breast cancer risk assessment by primary care physicians. As tools for breast cancer prevention continue to be developed, the diffusion of breast cancer risk assessment into primary care has gained increasing clinical importance.³³ This study demonstrates that current adoption seems to be largely related to the personal salience of breast cancer among physicians and practice characteristics, rather than attitudes about the strengths and limitations of current risk assessment methods. Strategies to increase the use of breast cancer risk assessment may need to focus on increasing the salience of breast cancer risk in primary care practice and on developing tools and systems that can support the use of these tools among diverse practice sites. Ongoing research into better methods of breast cancer screening and prevention, as well as the identification of new genetic and environmental risk factors, are likely to change the paradigm of breast cancer risk reduction in primary care. These developments may serve to increase the salience of breast cancer risk assessment to the average primary care provider, but they must also be accompanied by strategies and tools to facilitate their efficient incorporation into primary care practice if they are to reach their full potential in reducing breast cancer mortality.
