National Survey of Decision-Making for Antidepressants and Educational Level

Suzanne Brodney, PhD, RD, Floyd J. Fowler Jr, PhD, Vickie Stringfellow, BA, K. D. Valentine, PhD, and Michael J. Barry, MD

Background: Despite recommendations to screen adults for depression in primary care, little is known about how people across education levels decide to treat their depression and factors that influence their decision.

Methods: We conducted a secondary analysis of a national, probability-based web survey in English-speaking adults aged 40 or older living in the United States who reported they discussed starting or continuing an antidepressant with their clinician in the past 2 years. Respondents answered questions about knowledge, decision-making process, and demographics. Education level was analyzed using 5 ordered categories. The Shared Decision Making (SDM) Process score was used to assess patient involvement. Descriptive statistics, χ^2 tests, analysis of variance, and regression models were used to describe the data and test associations.

Results: Of the 5682 people invited, 3396 answered questions about health decisions (59.8% response rate) and 385 reported discussing antidepressants. The mean percentage of knowledge questions answered correctly increased as education level increased ($P = .008$). The mean SDM Process score also increased with education ($P = .001$). There was an association between education and who made the treatment decision, suggesting that for respondents with less education, the clinician was more likely to decide ($P = .001$). Respondents with less education were less likely to report they would definitely make the same decision again ($P = .000$).

Conclusions: Those with less education were even less informed, had lower SDM Process scores and were less likely to think they made the right decision about antidepressants. There is a need to ensure patients are better informed about and involved in treatment for depression. (J Am Board Fam Med 2020;33:80–90.)

The US Preventive Services Task Force recommends screening adults in the general population for depression, including older adults and pregnant

and postpartum women, concluding that screening is of moderate net benefit. However, screening should be implemented with adequate systems in place to ensure accurate diagnosis, effective treatment, and appropriate follow-up.¹ Results from the 2015 National Survey on Drug Use and Health estimated that in the past year about 16.1 million adults had at least 1 major depressive episode.² Mental disorders were listed as the costliest condition for institutionalized and noninstitutionalized populations.³ The majority of those seeking treat-

ment for depression do so in primary care,⁴ although the most effective interventions to increase depression treatment initiation in primary care are unclear.⁵

Once a patient is screened for depression and identified as requiring follow-up, patients and providers have a variety of pharmacologic and non-pharmacologic treatment choices to consider.^{6–8} The practice guideline from the American College of Physicians recommends cognitive behavioral therapy or a second-generation antidepressant after discussing the options with the patient and incorporating the patients' preferences.⁶ Despite the available options, less than one-third of people identified as depressed receive treatment.⁹ Many cases of screen-detected depression will be at the milder end of a severity spectrum within Major Depressive Disorder. For these individuals, the efficacy of antidepressant treatment seems limited.¹⁰ A recent commentary offers suggestions for helping physicians in primary care settings address depression treatment options and uncertainties.¹¹

There is limited evidence on how involved people are with the decision to treat their depression and the factors that influence whether or not the decision aligns with the patients' values and preferences. Results from a meta-analysis of patient preferences for psychiatric disorders reported that overwhelmingly patients prefer psychological treatment compared with pharmacologic treatment.¹² Hines and colleagues¹³ compared audiotapes of postvisit surveys from patients and their clinicians. They found that only 9% of depression-related treatment decisions met the basic elements of informed decision making.

Shared decision making (SDM) has been identified as an approach to help patients and clinicians with the decision to treat depression. SDM, which is a communication process by which patients work with clinicians to make better health decisions, has 3 core components: (1) clear, accurate, and unbiased medical evidence about the reasonable alternatives, including no intervention, and the risks and benefits of each option; (2) expertise in communicating and personalizing that evidence to the individual patient; and (3) patients' goals, concerns, and informed preferences.¹⁴ SDM has been reported to be better than usual care as a method to improve decision making for depression treatment,^{15–17} but survey data exploring to what extent SDM occurs

in primary care for depression indicate SDM is underutilized.^{18–20}

Making a high-quality treatment decision includes understanding basic facts about the condition and treatment choices. Cross-sectional studies of adults show that on average patients are poorly informed and not very involved in their treatment decisions.^{21–23} People with less formal education have significantly less knowledge about their options than others.²⁴ In a medically underserved population, patients with lower health literacy were less likely to engage in decision making.²⁵

The purpose of this analysis was to explore the association between depression treatment, education level, and the patient role in the treatment decision, in terms of being informed and involved. We hypothesized that respondents with less education would be less informed about their condition and treatment options, less involved in the decision-making process, and experience more dissonance between their preferred and the actual treatment decision compared with those with more education.

Methods

Study Population and Data

The data for this secondary analysis were collected as part of the TRENDS survey, which was conducted between November and December 2011 by Knowledge Networks using a probability-based web panel designed to be representative of adults aged 40 and older living in US households. This is a secondary analysis of individuals who responded that they engaged in a decision about depression treatment. The methodology has been previously published.²⁶ This survey only included people who could respond in English. The survey was reviewed and approved by New England Independent Review Board.

Briefly, Knowledge Networks sampled households from its KnowledgePanel to represent a cross-section of adults 40 or older in the United States. Both random-digit dialing and address-based sampling were used to recruit the original panel. People who were recruited but did not have computers or Internet service were provided with both so that the samples did not exclude those who lacked Internet access. Once the respondents were invited to participate, they answered a set of questions to identify those who had experienced or had had discussion with a medical provider regarding at least 1 of 10 decisions in the past 2 years. These

included being screened for colorectal, breast, or prostate cancer; starting or stopping medication for hypertension, high cholesterol, or depression; having a knee or hip replacement for osteoarthritis; or having surgery for cataracts or low back pain. Those not meeting the criteria were excluded from further participation. Those who were eligible continued with the main survey. When respondents reported being eligible for the survey based on more than 1 topic, a probability selection was made of 2 topics to address in the survey, with the less common decisions being given a higher probability of selection. This analysis focuses on the 385 respondents who completed the depression survey after reporting a discussion with a health care provider in the past 2 years about starting or continuing antidepressant medication.

Main Measures

The survey gathered data on demographic characteristics, including age, sex, race, education, marital status, work status, household income, health insurance status, and self-reported health. Education was stratified into 5 categories: less than high school graduate, high school graduate, some college, college graduate, and graduate work. Scales were included to determine to what extent respondents were informed and involved and would make the same decision about antidepressant treatment again.

Informed

To explore how informed respondents were about their depression treatment options, they were asked 5 knowledge questions (4 multiple choice and 1 fill in the blank). A score for each respondent was calculated based on the percentage answered correctly. The questions were developed by an experienced depression researcher and psychometricians to cover what they considered the most essential facts needed in order make an informed treatment decision. These questions were first used as part of the DECISIONS study²⁶ conducted by the University of Michigan in 2008 and were reviewed for currency in 2011. All questions were cognitively tested to make sure they were consistently understood. Knowledge questions that were not answered were considered incorrect. (Appendix)

Involved

An SDM Process score was calculated based on responses to 4 questions about how much the pros and cons of the decision were discussed, if the choices were explained, and if the provider asked what the respondent wanted to do. The score is based on questions first used in the DECISIONS study²⁷ and have been used in several subsequent studies.²⁸ The SDM Process score has been endorsed as a quality measure by the National Quality Forum (NQF) (<http://www.qualityforum.org/QPS/QPSTool.aspx>). A higher score indicates more involvement in the decision. For the NQF measure, a score of 3 (range, 0 to 4) or better has been considered “good.” One point each was assigned for discussing the pros and cons “a lot” or “some” and responding “yes” if the provider explained the choices and “yes” if the provider asked the respondent what treatment they wanted. Respondents were also asked who made the final decision about taking medication (the patient, the provider, or the decision was made together).

Make the Same Decision Again

To evaluate if respondents were comfortable with their actual treatment, they were asked if they would make the same decision about starting or stopping antidepressants again (definitely yes, probably yes, probably no, or definitely no).

Data Analysis

The survey results were designed to be representative of US English-speaking adults aged 40 and older who discussed starting or continuing medication for depression within 2 years of the survey. All results were weighted to adjust for differences in the probability of selection due to the number of decisions reported. Analyses were conducted using IBM SPSS Complex Samples Module, version 21, and R version 3.5.2.²⁹

The primary focus of the analysis was how knowledge and the decision-making process differed by the level of formal education reported by the respondent. Means and standard deviations were calculated for continuous variables, and frequencies were calculated for categorical variables. χ^2 analyses were conducted to explore the relationship between education level and categorical variables, including demographics, decision process, and comfort with the decision. Knowledge was assessed by examining the mean percent correct

based on the 5 knowledge questions. Analysis of variance was used to assess differences across education levels for the mean percent correct knowledge answers and the mean SDM Process scores. A simultaneous linear regression model was conducted to explore the relationship between education level and SDM Process score when adjusting for age, sex, ethnicity, income, health status, and insurance status. When data were checked for outliers, 1 outlying observation was identified, but results did not change with or without this observation, so it was allowed to remain in the dataset. All other assumptions were met for the model.

Results

Of the 5682 panel members asked to participate in the national survey, 3396 (59.6%) answered the

screening question whether they had discussed a decision with a health care professional. Of these members, 2788 reported making 1 or more decisions and 2718 then completed the survey (97.5% of those eligible). The overall response rate of 58.3% assumes nonrespondents were eligible at the same rate as screening question respondents. A total of 385 respondents who reported a discussion about antidepressant medication with their provider are included in this analysis.

Demographics

Table 1 describes the characteristics of the respondents who made a decision about antidepressant medication. About two-thirds of the sample was less than 60 years of age, and a similar percentage was female. Age and sex did not differ significantly

Figure 1. Mean percent of knowledge questions answered correctly.

across education levels. The majority of participants in each education level were non-Hispanic white. Education was directly and significantly related to the likelihood of being employed, and there was a strong monotonic relationship between education and family income. There was no difference in the percentages with health insurance across education levels. Although those with less education reported lower health status than those with more education.

Informed

Across education categories, respondents were poorly informed about the key facts of depression treatment (Figure 1). Regardless of education, the mean percentage of questions respondents answered correctly was well less than 50%. Only 16 of the 385 respondents answered 4 or more of the 5 questions correctly (data not shown). Across all respondents, the mean percent of knowledge questions answered correctly was significantly related to education ($F = 3.47$, $P = .008$).

Involved

The mean SDM Process score differed significantly across education levels ($F = 4.92$, $P = .001$); mean scores rose monotonically from the lowest education group to the highest from 2.26 up to 3.22 on the 4-point scale (Table 2). For the top 2 education strata, the mean SDM Process score was in the “good” range based on the scoring as an NQF measure. When the components of the score were explored individually, there were significant differences in how much respondents reported that providers discussed the cons of taking antidepressants (41% of respondents in the lowest education level reported “not at all” compared with 10% of re-

spondents in the highest). Similarly, for those in the lowest education level, 25% reported that the provider did not explain the choices compared with 17% in the highest. When asked if the provider asked them whether or not they wanted to start or continue taking an antidepressant, 57% of those in the lowest education level reported that they were not asked compared with 24% in the highest level. Furthermore, when entered into a linear model, having more education was found to be related to higher SDM Process scores ($b = 0.13$, $P < .001$) when adjusting for other demographic variables, including race and ethnicity.

Consistent with those results, the more formal education respondents had, the more likely they were to say that they mainly made the decision about an antidepressant themselves (59% vs 35%), whereas those with less formal education were more likely to say their providers mainly made the decision (27% vs 2%).

Make the Same Decision Again

Finally, when asked if they would make the same decision again about antidepressants, there was a clear relationship indicating that the higher the respondents’ education, the more likely they were to say that they would “definitely” make the same decision again (70% in the highest education level vs 53% in the lowest education level, $P < .000$). Compared with those with the highest education level, those in the lowest education level were more likely to report they would “definitely not” make the same decision again (15% vs 3%).

Discussion

Our hypotheses were that people with less formal education who had made a decision about starting

or stopping antidepressants would be less informed, less involved, and less likely to report they would make the same decision again. Regardless of educational level, respondents were not well informed about their condition and treatment options, and those with less education were even less informed. Compared with those with higher education, those with less education were also less involved in the decision to start or continue taking antidepressant medication, more often reported the provider made the final decision, and less likely to report they would make the same decision again. After adjusting for other demographic factors, including race and ethnicity, the significant relationship between SDM Process and education level remained.

Prior national surveys of medical decision making indicate that people often do not know basic facts about common medical decisions they have

made.^{23,24} A recent review of decision making needs in patients with depression and schizophrenia reported that patients have an unmet need for information about basic facts, treatment, and coping, as well as decisions about medication and treatment setting.³⁰ Patients and clinicians also have different perceptions of what is most important for patients to know about their treatment.¹⁹ Having an objective measure of facts about a decision is crucial to making an informed decision. The knowledge questions used in this survey may be imperfect, but they represent one reasonable and thoughtful effort to define the information needed to make an informed decision.

Across a range of treatment and screening decisions, patients are often not optimally included.^{22,23,26,31} Similar to other medical decisions, respondents reported that clinicians discussed the

pros of antidepressant treatment more than the cons.²⁷ In this analysis, for those with less formal education, the cons of the decision were discussed less often compared with those with more education. For example, 41% in the lowest education level reported no discussion of cons at all, compared with 10% in the highest education category. In addition, the less educated the patient, the less participation in the decision they reported. Lower educated respondents reported that clinicians included them in the decision about half as often as higher educated patients (43% vs 76%). The survey was conducted in 2011. Since that time, SDM may have improved such that our data do not reflect what is actually happening in clinics now. However, we are not aware of any data documenting such an improvement.

Increasing patient engagement by offering educational information that is accessible to all should help to minimize the gap observed by those with education levels. In 2015 Wexler and colleagues³² published a manuscript describing patient responses to decision aids in the United States. Participants were 3001 patients from 6 primary care sites across the United States who were facing 1 of 16 common medical decisions. In this sample, which included 33% of patients with a high school education or less, giving patients decision aids resulted in patients achieving knowledge scores at least as high as those who had obtained a higher level of education.

Importantly, a lack of involvement in the treatment decision may impact adherence to antidepressant medication once it is prescribed.³³ Jaffray and colleagues³⁴ conducted a qualitative study with patients recently started on antidepressants looking at why patients discontinued their treatment. Ownership, knowledge, and support were found to be the main factors impacting why patients adhere to treatment and that joint decision making was associated with more positive attitudes toward antidepressant use. These data show that because of the way physicians and patients interact, those with less education are likely to be disadvantaged with respect to commitment and ownership of the decision to take antidepressants.

With increasingly widespread screening for depression in primary care, driven in part by clinical practice guidelines, it is important to ensure subsequent decisions about treatment, particularly for screen-detected cases, are of high quality. The re-

sults of this study suggest substantial room for improvement in helping all patients, but more specifically those with less formal education, to understand what a diagnosis of depression means, the pros and cons of the treatment options, and how to incorporate the patient's treatment preference. One method to improve communication is to offer patients certified patient decision aids, which have been proven to improve outcomes.³⁵ In populations where there is a disparity in who receives treatment, patient decision aids have helped align the patient's treatment preference to the treatment received.^{36,37}

Identifying and/or creating patient decision aids that meet certification criteria, addressing the decisions relevant to what patients are faced with, and ensuring the tools are accessible to people with lower education levels are all necessary. Clinicians should also be trained in how to engage in SDM to ensure that patients educated about SDM do not encounter a system that is not willing to include them in the process. System changes are also necessary to optimize how and when patients receive decision support materials.

There are limitations to our analysis. The data, which were collected in 2011, may now differ because of the increased focus on depression awareness, screening, and treatment, although it seems unlikely that the patterns of interaction between patients and physicians we describe have fundamentally changed. The survey only included English-speaking adults, but one would hypothesize that these issues may be even more problematic for those who do not speak English. The content of the conversations between patients and physicians was not recorded, so these data are based on patient reports about their knowledge and interactions that occurred, on average, a year before the interview. It is possible that the 2-year recall period could have impacted respondents' answers; however, a recent analysis by Sepucha and colleagues³⁸ found that timing of measurement on decision quality and SDM did not show a difference in mean knowledge scores between 1 month and 1 year. We also acknowledge the possibility of nonresponse bias from the original sample, which would impact the generalizability of our findings. The sample from Knowledge Networks should be representative, but because respondents self-selected into the study panel, there is a possibility that those who were invited but did not self-select are different from

those who were invited to the panel and agreed to participate.

Conclusion

The majority of respondents were poorly informed about their treatment options for depression. Those with less education were even less informed, had lower SDM Process scores, were more likely to think the doctor made the decision, and were less likely to think they made the right decision. As more patients are identified through screening, there is a need to ensure patients are better informed about and involved in treatment for depression.

This work was presented as a poster at the Society for Medical Decision Making annual meeting in October 2017 in Pittsburgh, PA.
